Abstract

Are the forms of words systematically related to their meaning? The arbitrariness of the sign has long been a foundational part of our understanding of human language. Theories of communication predict a relationship between length and meaning, however: Longer descriptions should be more conceptually complex. Here we show that both the lexicons of human languages and individual speakers encode the relationship between linguistic and conceptual complexity. Experimentally, participants mapped longer words to more complex objects in comprehension and production tasks and across a range of stimuli. Explicit judgments of conceptual complexity were also highly correlated with implicit measures of study time in a memory task, suggesting that complexity is directly related to basic cognitive processes. Observationally, judgements of conceptual complexity for a sample of real words correlate highly with their length across 80 languages, even controlling for frequency, familiarity, imageability, and concreteness. While word lengths are systematically related to usage—both frequency and contextual predictability—our results reveal a systematic relationship with meaning as well. They point to a general regularity in the design of lexicons and reinforce the importance of cognitive constraints on language evolution.

Keywords: communication, lexicon, language evolution

Introduction

Human languages are systems for encoding information about the world. A defining feature of a symbolic coding system is that there is no inherent mapping between the form of the code and what the code denotes (Peirce, 1931)—the color red holds no natural relationship to the meaning ‘stop’, the numeral 3 holds no natural relationship to three units, and in language, the word ‘horse’ looks or sounds nothing like the four-legged mammal it denotes. The arbitrariness of the linguistic sign has long been observed as a fundamental and universal property of natural language (Saussure, 1916, 1960; Hockett, 1960). And, despite the growing number of cases suggesting instances of non-arbitrariness in the lexicon (Schmidtke, Conrad, & Jacobs, 2014, for a review), there is clear evidence for at least some degree of arbitrariness in language based only on the observation that different languages use different words to denote the same meaning (e.g. the word for horse in English is “horse” but is “at” in Turkish).

Importantly, however, the arbitrary property of language is true only from the perspective of the outside analyst. From the perspective of the language user, language is highly non-arbitrary; there are strong constraints on how language is used in particular instances of communication. A rich body of theoretical work has explored regularities in the use of particular forms to refer to particular types of meanings in context—the study of *pragmatics* (Grice, 1975; Horn, 1984; H. H. Clark, 1996). Broadly, this work argues that language users assume certain regularities in how speakers refer to meanings, and through these shared assumptions, the symmetry of the otherwise arbitrary character of language is broken. For example, consider a speaker who intends to refer to a particular apple on a table. Because language is *a priori* arbitrary, there are a range of ways the speaker could convey this meaning (e.g., “the apple,” “the banana,” “the green apple,” “the green apple next to the plate,” etc.), but the speaker is constrained by pragmatic pressures of the communicative context. If the listener also speaks English, the phrase “the banana” will be an unhelpful way to refer to the apple. Furthermore, if there is only one apple on the table, the phrase “the green apple” will be unnecessarily verbose given the referential context. These constraints

might lead a speaker to select “the apple” as the referential phrase, because it both allows the listener to correctly identify the intended referent while also minimizing effort on the part of the speaker.

In the present paper, we examine whether principles of communication influence the otherwise arbitrary mappings between words and meanings in the lexicon. In particular, we explore a communicative regularity first observed by Horn (1984): pragmatic language users tend to consider the effort that speakers have exerted to convey a meaning. For example, the utterance “Lee got the car to stop” seems to imply an unusual state of affairs. Had the speaker wished to convey that Lee simply applied the brakes, the shorter and less exceptional “Lee stopped the car” would be a better description. The use of a longer utterance licenses the inference that there was some problem in stopping—perhaps the brakes failed—and that the situation is more complex. Do we reason the same way about the meanings of words, breaking the symmetry between two unknown meanings by reference to length? In other words, is a “tupabugorn” more likely to be a complex, unusual object than a “ralex”? We examine whether this regularity—a *complexity bias*—is present in the lexicon.

The present hypothesis is motivated by the possibility that language dynamics take place over different timescales, and these different dynamics may be causally related to each other. Minimally, two timescales are relevant to the present hypothesis. At the shorter timescale are the minutes of a single communicative interaction—the *pragmatic timescale*. At the longer timescale is language change, which takes place over many years—the *language evolution timescale*. We consider the possibility that communicative pressures at the pragmatic timescale may, over time, influence the structure of the lexicon at the language evolution timescale. There are other reasons why a regularity like a complexity bias might emerge in the structure of the lexicon, however, and we consider some of these alternative possibilities in the General Discussion.

An important construct for our hypothesis is the notion of conceptual complexity. In Studies 1 and 2, we appeal to an intuitive notion of complexity by manipulating conceptual complexity

indirectly in terms of visual complexity. We find that our visual manipulations are highly correlated with explicit measures of complexity and reliable across participants. Nonetheless, these manipulations are likely only proxies for an underlying cognitive construct. We could imagine a space of possible meanings as compositional semantic primitives, as opposed to visual primitives. In this space, a more complex meaning would be one with more primitives in it. (In a probabilistic framework, having more units would also be correlated with having a lower overall probability). [these two sentences are from the cogsci paper] In Study 3, we try to more directly examine the cognitive correlates of conceptual complexity through reaction time.

The plan of the paper is as follows. We first review prior work suggesting that communicative principles are reflected in the structure of the lexicon. We then review work related to accounts of our particular linguistic feature of interest—variability in the length of forms. Next, we present four sets of studies that explore a complexity bias in the lexicon. In Studies 1 and 2, we experimentally test whether participants are biased to map a relatively long novel word onto a relatively more complex object, using artificial objects (Study 1) and novel, real objects (Study 2). In Study 3, we explore the underlying cognitive construct of complexity in a reaction time task. Finally, in Study 4, we examine a complexity bias in natural language through a corpus analysis of 80 languages.

Pragmatic equilibria in the lexicon

Several broad theories of pragmatics include a version of two distinct pressures on communication: the desire to minimize effort in speaking (*speaker pressure*) and the desire to be informative (*hearer pressure*; Zipf, 1936; Horn, 1984). Importantly, these two pressures tradeoff with each other: the optimal solution to the speaker’s pressure is a single word that can refer to all meanings, while the optimal solution to the hearer’s pressure is a verbose, minimally ambiguous phrase. The utterance that emerges is argued to be an equilibrium between these two tradeoffs.

At the timescale of language evolution, there a number of cases in which these pragmatic

equilibria are reflected in the lexicon. One way these equilibria are reflected is in the size of the semantic space denoted by a particular word. From the hearer's perspective, Horn argues there is a pressure to narrow semantic space (Horn, 1984). This reflects the idea that the hearer's optimal language is one in which every possible meaning receives its own word. One example of this is the word "rectangle." This word refers to a quadrilateral with four right angles. A special case of a "rectangle" is a case where the four sides are equal in length, which has its own special name, "square." Consequently, the term "rectangle" has been narrowed to mean a quadrilateral with four right angles, where the four sides are *not* equal. From the speaker's perspective, there is a pressure for semantic broadening. This is because the speaker's ideal language is one in which a single word can refer to a wide range of meanings. An example of this is the broadening of brand names to refer to a kind of product. For example, "kleenex" is a name of a product name for facial tissues, but has taken on the meaning of facial tissues more generally.

The opposition of these two semantic forces predicts an equilibrium in the organization of semantic space that satisfies the pressures of both speaker and hearer. A body of empirical work has tested this prediction by examining the organization of particular semantic domains cross-linguistically (Regier, Kemp, & Kay, 2014). Languages show a large degree of similarity in how they partition semantic space for a particular domain, but they also show a large degree of variability. The attested systems can be shown to all approximate an equilibrium point between speaker and hearer pressures.

Kemp and Regier (2012) demonstrate this systematicity in the semantic domain of kinship. For each language, they developed a metric of the degree to which Horn's speaker and hearer pressures are satisfied. A language that better satisfies the hearer's pressure is one that is more complex, as measured by the description length of the system in their representational language. A language that better satisfies the speaker's pressure is one that requires less language to describe the intended referent. To understand this, consider the word "grandmother" in English: this word is ambiguous in English because it could refer to either the maternal or paternal mother, and so

identifying one in particular is more costly in English than in a language that encodes this distinction lexically. They find that the set of attested languages is a subset of the range of possible languages, and this subset partitions the semantic space in a way that is near the optimal tradeoff between pragmatic pressures. This type of analysis has also been done for the domains of color (Regier, Kay, & Khetarpal, 2007), light (Baddeley & Attewell, 2009), and numerosity (Xu & Regier, 2014).

A second phenomenon that is predicted by these forces is cases where there are multiple meanings associated with a word from a context-independent perspective, or cases of lexical ambiguity. Lexical ambiguity is present in both open-class words like “bat” (a baseball instrument or a flying mammal) and closed-class quantifiers like “some” (“at least one and possibly all” or “at least one but not all”). Lexical ambiguity is tolerated because the meaning is usually easily disambiguated by context. When the word “bat” is uttered while watching a baseball game, the mammal usage of the word is very unlikely. The presence of this type of ambiguity can be viewed as an equilibrium between the two pragmatic pressures. If the meaning of a word can be disambiguated by the referential context, then it would violate the speaker’s pressure to minimize effort by keeping track of two distinct words.

Indeed, recent work by Piantadosi, Tily, and Gibson (2011a) reveals systematicity in the presence of lexical ambiguity in language. They argue that ambiguity results from a speaker based pressure to broaden the meaning of a word to include multiple possible meanings. In particular, they suggest that this pressure should lead to a systematic relationship between the presence of ambiguity and the cost of a word. According to their argument, costly words (in terms of length, frequency, or any metric of cost) that are easily understood by context violate the speaker’s principle to say no more than you must. Consequently, there should be a pressure for these meanings to get mapped on to a different, less costly word. This word may happen to already have a meaning associated with it, and so the result is multiple meanings being mapped to a single word. For example, in the case of the word “bat,” a speaker could instead say “baseball bat.” But, because

this referent is easily disambiguated in context from the mammalian meaning, Horn's speaker principle provides a pressure to use the shorter form. This leads to a testable prediction that shorter words should tend to be more ambiguous. Through corpus analyses, Piantadosi et al. (2011a) find this precise relationship between cost and ambiguity. Across English, Dutch and German, they find that shorter words are more likely to have multiple meanings.

An additional case of this lexical ambiguity is found in words that have very little context-independent meaning, known as indexicals or deictics (Frawley, 2003). These words get their meaning from the particular referential context of the utterance, and are therefore highly ambiguous from a context-independent perspective. There are many types of indexicals that are present to varying degrees across languages. An example of a temporal indexical form is "tomorrow." The context-independent meaning of this word is something like "the day after the day this word is being uttered in." Critically, abstracted from any context, this word has little meaning; it is impossible to interpret without having knowledge about the day the word was uttered. This phenomenon is also present in person pronouns (e.g. "you" and "I") and spatial forms, like "here" and "there." As for lexical ambiguity, this type of ambiguity is a predicted equilibrium point from Horn's principles: If the hearer can recover the intended referent from context, the speaker would be saying more than is necessary by using an overly-specific referential term (e.g., "December 18th, 2014" vs. "tomorrow"). Language structure reflects this pressure through lexicalized ambiguity in the form of indexicals.

Finally, the relationship between the meanings of different words can be seen as a consequence of pragmatic principles. A number of theorists have noted a bias against two words mapping onto the same meaning — that is, a bias against synonymy (Saussure, 1916, 1960; Kiparsky, 1983; Horn, 1984; E. Clark, 1987, 1988). This bias is an equilibrium between Horn's speaker and hearer principles. Recall that the optimal language for a hearer is one in which each meaning maps to its own word — exactly a language biased against synonymy. It turns out that the speaker's pressure also biases against synonymy. The optimal language for the speaker is a

language where a single word maps to all meanings. But, a case where multiple words map to a single meaning is also undesirable because the speaker must keep track of two words. So, for both the speaker and the hearer, there is pressure to avoid synonymy. Thus, when a listener hears a speaker use a second word for an existing meaning, the hearer infers that this could not be what the speaker intended because this would violate the speaker's principle. The result is an assumption that the second word maps to a different meaning. This pattern is reflected in language structure by a one-to-one pattern in the lexicon — that is, a structure in which each word maps to exactly one meaning and each meaning maps to exactly one word.

As one kind of evidence for this one-to-one structure in the lexicon, Horn (1984) points to a phenomenon called *blocking*. Blocking refers to cases in which an existing lexical form blocks the presence of a different, derived form with the same root. Consider the following examples:

(a) fury furious *furiosity

(b) *cury curious curiosity

In both (a) and (b), forms that would be expected, given the inflectional morphology in English, are not permitted. This is due to the fact that they would have the same meaning as the existing form because they have the same root. Examples such as this provide some evidence for a one-to-one structure in language, but a one-to-one structure is a particularly difficult linguistic regularity to test empirically. Nonetheless, it is an important regularity because it licenses certain inferences in interpreting the meaning of words. In particular, the cognitive representation of a lexical one-to-one regularity—*mutual exclusivity*—has been posited as a powerful bias in children's word learning (Markman & Wachtel, 1988; Markman, Wasow, & Hansen, 2003).

Together these phenomena—semantic organization, ambiguity, and one-to-one structure—provide three cases in which equilibria that are predicted by theories of communication at the pragmatic timescale are reflected in the structure of the lexicon at the language evolution timescale. While this commonality does not entail causality, it is suggestive of a causal relationship between the two timescales. Next, we turn to accounts at both the pragmatic and language

evolution timescale for our particular phenomenon of interest: variability in language length.

Accounts of language length variability

Language forms vary along many dimensions, but a salient dimension is length: words and entire utterances can have dramatically different phonetic lengths. At the pragmatic timescale, several theories of communication predict that longer expressions should be associated with less predictable or typical meanings than their shorter counter parts.

One such theory is Horn's theory of communication (1984). A speaker often has the choice of using two different utterances to refer to the same meaning (in truth functional terms), and often these utterances differ in length. Horn presents the following example:

- (a) Lee stopped the car.
- (b) Lee got the car to stop.

Both (a) and (b) have the same denotational meaning (the successful stopping of a car), but they differ in length ((b) has two extra words). Horn argues that this asymmetry leads to an inference on the part of the listener that the two differ in meaning. The logic of this inference is identical to the lexical structure case above. The listener hears a speaker use a more costly phrase to express a meaning that could have been expressed in a less costly way. The listener thus infers that this other meaning could not be what the speaker intended because this would violate the speaker's principle to say no more than is necessary. Horn adds an additional layer to this argument. He suggests that not only do these two forms differ in meaning, but that they map onto meanings in a systematic way. In particular, he argues that the longer form gets mapped on to the more marked meaning, while the shorter form refers to the unmarked meaning. The notion of 'markedness' is underspecified here, but an intuitive definition is related to complexity: more marked things are more conceptually complex, while less marked things are more conceptually simple. Thus, in the above example, (a) would refer to a simple, average case of car stopping, while (b) might refer to a case where something complex or unusual happened, perhaps because Lee used the emergency brake.

The source of the particular mapping between forms of different lengths and meanings of different degrees of markedness is unclear. This is because, in principle, there are multiple equilibrium points in the mapping between form and meaning. Assuming a one-to-one constraint on the mapping, there are two possible equilibria: {short-simple, long-complex} or {short-complex, long-simple}. Both satisfy the constraint that each form gets mapped to a unique meaning. So how do speakers arrive at the {short-simple, long-complex} equilibrium? This is difficult to derive from models of pragmatic reasoning. G. Bergen Levy (in prep) successfully derive this result as a consequence of the fact that {short-simple, long-complex} is a more optimal mapping for the speaker. Another possibility relies on iconicity: hearers have a cognitive bias to map more complex sounding forms to meanings that are similarly complex.

L. Bergen, Goodman, and Levy (2012) provide a direct test of the length-complexity tradeoff within a communication game. In their task, partners were told that they were in an alien world with three objects and three possible utterances. In this experiment, the idea of complexity was operationalized as frequency, such that participants were instructed that each of the three different objects had three different base rate frequencies associated with them. The cost of the utterance was manipulated directly (rather than through utterance length) by assigning different monetary costs to each object. Participants' task was to communicate about one of the objects using one of the available utterances. If they successfully communicated, they received a reward. The results suggest that both the speaker and hearer expected costlier forms to refer to less frequent meanings, consistent with Horn's predicted equilibrium between word length and meaning.

The prediction of a complexity bias at the pragmatic timescale falls more directly out of information theory. Information theory models communication as the transfer of information across a noisy channel (Shannon, 1948). Under this theory, speakers optimize information transfer (in terms of bits) by keeping the amount of information conveyed in a unit of language constant across the speech stream. A straightforward consequence of this *uniform information density* assumption is that speakers should try to lengthen unpredictable utterances. There is evidence for

this prediction across multiple levels of communication. At that level of prosody, speakers tend to increase the duration of a word in cases where the word is unpredictable (highly informative) given the linguistic context (Aylett & Turk, 2004). There is also evidence for this prediction at the level of syntactic (Frank & Jaeger, 2008) and discourse predictability (Genzel & Charniak, 2002).

At the timescale of language evolution, there is some indirect evidence that this same bias is present in the lexicon. These approaches use the linguistic context of a word as an indirect measure of the complexity of meaning. The idea is that words that are highly predictable, given the linguistic context, have more complex meanings, while words that are less predictable given the linguistic context, have less complex meanings. Piantadosi, Tily, and Gibson (2011b) measured the relationship between the predictability of words in context and the length of words. Across 10 languages, these two measures were highly correlated: words that were longer were less predictable in their linguistic context on average. This result held true even controlling for the frequency of words. Additional evidence for this relationship comes from examining pairs of words that have very similar meaning, but differ in length (e.g. “exam” vs. “examination;” Mahowald, Fedorenko, Piantadosi, & Gibson, 2012). Through corpus analyses, they find that the longer forms are used in less predictable linguistic contexts. They also find in a behavioral experiment that speakers are more likely to select the longer word in unsupportive contexts. This body of work points to a systematic relationship between word length and meaning, when complexity is operationalized as predictability in the linguistic context.

[should frequency be talked about anywhere as a correlate of language length at the language evolution timescale (in light of the Piantadosi result)?]

[TO DO: paragraph on markedness]

Thus, at the pragmatic timescale, there is a well-motivated prediction that less predictable meanings should be described with longer utterances. At the language evolution timescale, there is some indirect evidence that longer words refer to less predictable meanings, but no work directly tests this prediction. This was the goal of the present studies. In the set of four studies described

below, we test the hypothesis that longer words refer to less predictable or complex meanings—a complexity bias—and find evidence for this bias both experimentally with novel words (Studies 1-3) and observationally in the lexicons of 80 natural languages (Study 4).

Study 1: Complexity bias with artificial objects

As a first step in exploring a complexity bias, we manipulated the complexity of objects and asked participants to infer their names. Object complexity was manipulated by varying the number of primitive parts the objects were composed of. If participants have a complexity bias, we predicted they should be more likely to map a longer novel word onto an object composed of more parts, compared to an object with fewer parts. In Experiment 1a, we first conducted a norming study to verify our intuitions that the number of object parts correlated with explicit judgements of complexity. In Experiment 1b, we used these normed stimuli in a simple word mapping task, revealing a robust complexity bias. Experiment 1c replicated Experiment 1b with randomly concatenated syllables.

Experiment 1a: Object complexity norms

Methods

Participants. In this and all subsequent experiments, participants were recruited on Amazon Mechanical Turk and received US \$0.15-0.30 for their participation, depending on the length of the task. 60 participants completed this first experiment.

Across all experiments, some participants completed more than one experiment. The results presented here include the data from all participants, but all reported results remain reliable when excluding participants who completed more than one study. Participants were counted as a repeat participant if they completed a study using the same stimuli (e.g., completed both Experiment 1a and 1b with geons).

Figure 1. Stimuli in Experiment 1. Each row corresponds to a complexity condition. The complexity condition is determined by the number of “geon” parts the object contains (1-5).

Stimuli. As object primitives, we used “geon” shapes which are argued to be primitives in the visual system under one theory of object recognition (Biederman, 1987). We created a set of 40 objects containing 1-5 geon primitives (Figure 1)¹.

Procedure. We presented participants 12 objects from the the full stimulus set one at a time. For each object, we asked “How complicated is this object?,” and participants responded using a slider scale anchored at “simple” and “complicated.” Each participant saw two objects from each complexity condition, and the first two objects were images of a ball and a motherboard to anchor participants on the scale.

Results and Discussion

Number of object parts was highly correlated with explicit complexity judgement ($r = .93$, $p < .0001$; $M = .47$, $SD = .18$). Figure 2a shows the mean complexity rating for each of the 40 objects as a function of their complexity condition. This suggests that we can use manipulations of visual complexity as a proxy for manipulations of conceptual complexity.

¹All stimuli, experiments, raw data and analysis code can be found at REMOVED FOR BLIND REVIEW.

Figure 2. (a) The relationship between number of geons and complexity rating is plotted below. Each point corresponds to an object item (8 per condition). The x-coordinates have been jittered to avoid over-plotting. (b) Effect size (bias to select complex alternative in long vs. short word condition) as a function of the complexity rating ratio between the two object alternatives. Each point corresponds to an object condition. Conditions are labeled by the number of geons of the two alternatives. For example, the “1/5” condition corresponds to the condition in which one alternative contains 1 geon and the other contains 5 geons. (c) Proportion complex object selections as a function of the number of syllables in the target label. The dashed line reflects chance selection between the simple and complex alternatives. All errors bars reflect 95% confidence intervals, calculated via non-parametric bootstrapping in 1a and 1c, and parametrically in 1b.

Experiment 1b: Mapping task

Methods

Participants. 750 participants completed the experiment.

Stimuli. The referent stimuli were the set of 40 objects normed in Experiment 1a. The linguistic stimuli were novel words either 2 or 4 syllables (e.g., “bugorn” and “tupabugorn”) long. There were 8 items of each syllable length.

Procedure. We presented participants with a novel word and two possible objects as referents, and asked them to select which object the word named (“Imagine you just heard someone say *bugorn*. Which object do you think *bugorn* refers to? Choose an object by clicking the button below it.”).

Within participants, we manipulated word length and the relative complexity of the referent alternatives. We tested every unique combination of object complexities (1 vs. 2 geons, 1 vs. 3 geons, 1 vs. 4 geons, etc.), giving rise to 15 conditions in total. Each participant completed 4 short and 4 long trials in a random order, where each word was randomly associated with one of the complexity conditions. No participant saw the same complexity condition twice and no word or object was repeated across trials.

Results and Discussion

Across conditions, the more complex object was more likely to be judged the referent of the longer word. For each object condition (e.g., 1 vs. 2 geons), we calculated the effect size for participants’ complexity bias—the degree to which the complex object was more likely to be chosen as the referent of a long word, compared to the short word. Effect sizes were calculated using the log odds ratio (Sánchez-Meca, Marín-Martínez, & Chacón-Moscoso, 2003). Effect size was highly correlated with the ratio of object complexities: The greater the mismatch in object complexity, the more the longer word was paired with the more complex object ($r = -.87$,

$p < .0001$).

This experiment provides initial evidence for a complexity bias in the lexicon: Given an artificial word and two objects of differing visual complexity, participants are more likely to map a longer word onto a more complex referent, relative to a shorter word.

Experiment 1c: Control mapping task

One limitation of Experiment 1b is that it uses a small set of words as the linguistic stimuli (8 short and 8 long), making it possible that idiosyncratic properties of the words could be driving the complexity bias. In Experiment 1c, we sought to test this possibility by using words composed of randomly concatenated syllables rather than items selected from a small list of words.

Methods

Participants. 200 participants completed the experiment.

Stimuli. The referent stimuli were the geon objects composed of either 1 or 5 geons. The novel words were created by randomly concatenating 2, 4, or 6 consonant-vowel syllables (e.g., “nur,” “nobimup,” “gugotobanid”). The last syllable of all words ended in a consonant to better approximate the phonology of English.

Procedure. Participants completed six forced-choice trials identical to Experiment 1b. We tested only the “1/5” complexity condition (1-geon object vs. 5-geon object). Word length was manipulated within-participant such that each participant completed 2 trials for each of the three possible word lengths (2, 4, or 6 syllables).

Results and Discussion

Replicating the “1/5” condition in Experiment 1b, we found that participants were more likely to select a five geon object compared to a single geon object as the number of syllables in the

word increased ($\beta = -.44, p < .0001$). This suggests that the complexity bias observed in Experiment 1b is unlikely to be due to the particular set of words we selected.

Study 2: Complexity bias with novel real objects

Study 1 provides evidence for a complexity bias using artificial objects. The complexity manipulation in these experiments was highly-transparent, however, making it possible that task demands influenced the effect. We next asked whether this bias extended to more naturalistic objects, where the variability in complexity might be less obvious to participants. In Study 2, we conducted the same set of 3 experiments as in Study 1 using a sample of real objects without canonical labels. We find that the complexity bias observed with artificial geon objects in Study 1 extends to naturalistic objects. In Experiment 2d, we also find the same bias in language production.

Experiment 2a: Object complexity norms

Methods

Participants. We recruited two samples of 60 participants to complete Experiment 2a.

Stimuli. We collected a set of 60 objects that were real objects but that did not have canonical labels associated with them (Figure 3).

Procedure. The procedure was identical to Experiment 1a.

Results and Discussion

Complexity judgements were highly reliable across two independent samples ($r = .93, p < .0001; M_1 = .49, SD_1 = .18, M_2 = .44, SD_2 = .18$). Figure 4a shows the relationship between the complexity judgment for each item across the two samples of participants.

Figure 3. Study 2 stimuli: naturalistic objects without canonical labels. Each row corresponds to a quintile determined by the explicit complexity judgements obtained in Experiment 2a (top: least complex; bottom: most complex).

Experiment 2b: Mapping task

Methods

Participants. 1500 participants completed the experiment.

Stimuli. The linguistic stimuli were identical to Experiment 1b. The object stimuli were the 60 naturalistic objects normed in Experiment 2a. Five complexity conditions were determined by dividing the objects into quintiles based on the norms.

Procedure. The procedure was identical to Experiment 1b, except for the use of naturalistic rather than the artificial geon objects.

Results and Discussion

As with the artificial objects, effect size was negatively correlated with the complexity rating ratio between the referent alternatives ($r = .70, p < .005$; Fig. 4b). This suggests that the complexity bias observed with artificial objects extends to more naturalistic objects, consistent

Figure 4. (a) The correlation between the two samples of complexity norms. Each point corresponds to an object ($n = 60$). (b) Effect size (bias to select complex alternative in long vs. short word condition) as a function of the complexity rating ratio between the two object alternatives. Each point corresponds to an object condition. Conditions are labeled by the complexity norm quintile of the two alternatives. (c) The proportion of complex object selections as a function of number of syllables. The dashed line reflects chance selection between the simple and complex alternatives. All errors bars reflect 95% confidence intervals, calculated via non-parametric bootstrapping in 2a and 2c, and parametrically in 2b.

with the proposal that a complexity bias is a characteristic on natural language more generally.

The effect size in Experiment 2b is smaller than in Experiment 1b, however. This may be due to the fact that some of the effect in Experiment 1c was due to task demands associated with the transparent complexity manipulation. Nonetheless, Experiment 2b reveals a robust complexity bias with naturalistic objects.

Experiment 2c: Control mapping task

Methods

Participants. 200 participants completed the experiment.

Stimuli. The objects were 12 objects from the first and fifth quintile of complexity norms. The linguistic stimuli were constructed as in Experiment 1c.

Procedure. The procedure was identical to 1c, except for the different object stimuli.

Results and Discussion

Participants were more likely to select an object from the fifth quintile as opposed to the first quintile when the novel word contained more syllables ($\beta = -.34, p < .0001$; Fig. 4c). This pattern replicates the complexity bias seen in 2b with randomly concatenated syllables.

In the present experiment, participants were overall less likely to select the complex object, compared to the same experiment with artificial objects (Experiment 1c; STATS). One possible reason for this difference may be the fact that some of the simple artificial objects in Experiment 1c may be associated with canonical labels. For example, the sphere single-geon object may have evoked the label “ball.” If true, this might lead participants to appeal to mutual exclusivity in their object selections by selecting an object they do not already have a name for—in this case, the more complex object (Markman & Wachtel, 1988). Independent of this intercept shift, however, we replicate the complexity bias with random syllables in both studies.

Experiment 2d: Production task

Thus far we have observed the complexity bias only in comprehension tasks. In the next experiment, we ask whether the bias extends to language production. In Experiment 2d, we present participants with an object and asking them to produce a novel label to refer to it. Consistent with a

complexity bias, we find that participants produce longer labels for more complex objects. [not sure how to motivate the extension to production]

Methods

Participants. Fifty-nine participants completed the experiment.

Stimuli. The object were drawn from the set of 60 naturalistic objects used in Experiments 2a-c.

Procedure. In each trial, we presented with a single object and asked participants to generate a novel single-word label to refer to it. The instructions read: “What do you think this object is called? For example, someone might call it a ‘tupa’ or a ‘pakuwugnum.’ In the box below, please make up your own name for the object. Your name should only be one word. It should not be a real English word.” Each participant completed 10 trials—five objects from the bottom and top complexity norm quantiles each. Order of objects was randomized.

Results and Discussion

There were 26 productions (4%) that included more than one word. These productions were excluded. Length was measured in terms of log number of characters.

Participants produced novel coinages that were longer for the top quartile of objects ($M = 1.94$, $SD = 0.18$) compared to the bottom quartile ($M = 1.85$, $SD = 0.17$; $t(57) = 3.92$, $p < .001$). We also analyzed length as a function of the complexity norms for each object. Length of production was correlated with the complexity norms: Longer labels were coined for objects that were rated as more complex ($r = .17$, $p < .0001$). This suggests that the complexity bias extends to both language comprehension and production.

Study 3: Complexity as a cognitive construct

Studies 1 and 2 suggest that participants have a productive complexity bias when complexity is operationalized in terms of explicit norms. Next we sought to explore the cognitive construct of complexity. We reasoned that if complexity is related to a basic cognitive process, we should be able to measure it using an implicit task, not just via explicit ratings. In visual cognition, stimuli that contain more information require more processing time in search (Alvarez & Cavanagh, 2004; Hyman, 1953). To test this prediction, we measured participants' study time of objects in a memory task. Each participant studied half of the objects in the stimulus set, one at a time, and then made old/new judgments for the entire set. Critically, the study phase was self-paced, such that participants were allowed to study each object for as much time as they wanted. This study time provided an implicit measure of complexity. For both the artificial (Experiment 3a) and naturalistic (Experiment 3b) objects, we found that participants studied objects that were rated as more complex for longer.

Methods

Participants. 750 participants completed the task. 250 participants were tested with artificial geon objects (Experiment 3a) and 500 were tested with naturalistic objects (Experiment 3b).

Stimuli. The study objects were the set of 40 artificial geon objects (Experiment 3a) and 60 naturalistic objects (Experiment 3b).

Procedure. Participants were told they were going to view some objects and their memory of those exact objects would later be tested. In the study phase, participants were presented with half of the full stimulus set one at a time (20 geon objects and 30 naturalistic objects) and allowed to click a "next" button when they were done studying each object. After the training phase, we presented participants with each object in the full stimulus set (40 geon object and 60 naturalistic objects), and asked "Have you seen this object before?." Participants responded by clicking a "yes"

or “no” button.

Results and Discussion

Experiment 3a: Geon objects. We excluded subjects who performed at or below chance on the memory task (20 or fewer correct out of 40). A response was counted as correct if it was a correct rejection or a hit. This excluded 9 participants (4%). With these participants excluded, the mean correct was 72%. Participants were also excluded based on study times. We transformed the time into log space, and excluded responses that were 2 standard deviations above or below the mean. This excluded 4% of responses (final sample: $M = 7.40$, $SD = .66$).

Study times were highly correlated with the number of geons in each object ($r = .93$, $p < .0001$): objects that contained more geons tended to be studied longer. Study times were also highly correlated with the explicit complexity norms ($r = .89$, $p < .0001$): objects that were rated as more complex tended to be studied longer.

Study times did not predict memory performance. The study times for hits (correct “yes” responses; $M = 7.33$, $SD = .52$) did not differ from misses (correct “no” responses; $M = 7.34$, $SD = .59$; $t(223) = .61$, $p = .54$).

The critical question was whether or not mean study times for an object were related to the bias to assign a long or short word to that object. To explore this question, we reanalyzed the data from Experiment 1b in terms of study times instead of explicit complexity norms. The ratio of study times for the two object alternatives was correlated with the bias to choose a longer label ($r = .82$, $p < .001$; Fig. 5a): Relatively longer study times predicted longer labels.

Experiment 3b: Naturalistic objects. We excluded participants who performed at or below chance on the memory task (30 or fewer correct out of 60). A response was counted as correct if it was a correct rejection or a hit. This excluded 6 participants (1%). With these participants excluded, the mean correct was 84%. Participants were also excluded based on study times, using the same criteria as in Experiment 3a. This led to the exclusion of 4% of responses (final sample:

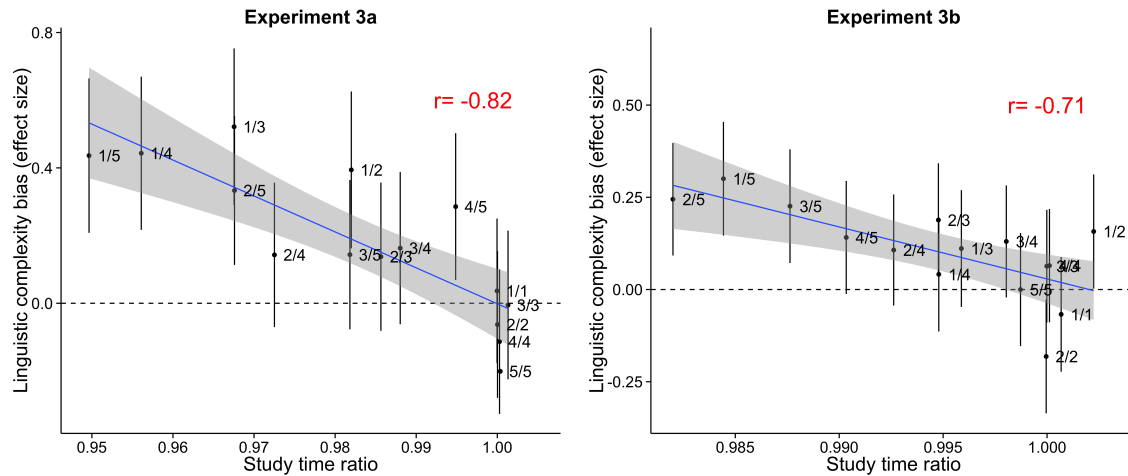

Figure 5. Effect sizes in Experiment 1b and 2b replotted in terms of study times collected in Study 3. Objects that are studied relatively longer are more likely to be assigned a longer label, relative to a shorter label. Error bars show 95% confidence intervals.

$M = 7.36, SD = .72$).

Study times were highly correlated with explicit complexity norms for each object. Like for the geons, objects that were rated as more complex were studied longer ($r = .54, p < .0001$).

Unlike for the geons, study times predicted memory performance. Study times for hits (correct “yes” responses; $M = 7.24, SD = .60$) were greater than for misses (correct “no responses; $M = 7.11, SD = .66; t(393) = 9.74, p < .0001$).

Critically, by reanalyzing data from Experiment 2b in terms of study times, we find that the ratio of study times for the two objects was correlated with the bias to choose a longer label ($r = .71, p < .005$; Fig. 5b).

Together, these findings suggest that label judgments are supported by basic cognitive processes related to the complexity or information content of a stimulus.

Together, these experiments point to a complexity bias in interpreting novel labels: Words

that are longer tend to be associated with meanings that are more complex, as reflected in both explicit and implicit measures.

Study 4: Complexity bias in natural language

Studies 1-3 revealed a productive complexity bias when participants are faced with novel words. Next we ask whether this bias extends to natural language. In Experiment 4a, we collected explicit complexity judgements on the meaning of 499 English words in a rating procedure similar to Experiments 1 and 2a above. Consistent with a complexity bias, we find that complexity ratings are highly correlated with word length in English: words with meanings that are rated as more complex tend to be longer. We then ask whether these complexity ratings correlate with word length in a sample of 79 languages. We find a complexity bias in all 79 languages, suggesting that this bias is a pervasive property of natural language.

Experiment 4a: English complexity norms

Methods

Participants. 246 participants completed the norming procedure.

Stimuli. We selected 499 English words from the MRC Psycholinguistic Database (Wilson, 1988) that were broadly distributed in their length and were relatively high frequency. This database includes norms for three other psycholinguistic variables: concreteness, familiarity, and imageability. This allowed us to compare our complexity norms to previously measured psycholinguistic variables.

Procedure. Participants were first presented with instructions describing the norming task:

In this experiment, you will be asked to decide how complex the meaning of a word is.

A words meaning is simple if it is easy to understand and has few parts. An example

of a simple meaning is “brick.” A word’s meaning is complex if it is difficult to understand and has many parts. An example of a more complex meaning is “engine.”

For each word, we then asked “How complex is the meaning of this word?,” and participants indicated their response on a 7-pt Likert scale anchored at simple and complex. The first two words were always ball and motherboard to anchor participants on the scale. Each participant rated a sample of 30 words English words. After the 17th word, participants were asked to complete a simple math problem to ensure they were engaged in the task.

Results and Discussion

direction of causality (long -i_ rated as more complex)
